## INTRODUCTION

Fine surface fuels play a major role in the ignition, spread, and intensity of fires. Fire behavior from ~1-m<sup>2</sup> to landscape (hectares) scales is driven by weather conditions and fuel characteristics, including fuel load, structure, moisture, and continuity. Understanding how fuel characteristics influence fire intensity, severity, and behavior is imperative for fire ecologists, modelers, and land managers where fire is an integral part of the landscape. However, specific information is know about relatively few species, and while valuable, this information is often obtained by studies conducted across a spectrum of realism. Methods range from *in situ* approaches where measurements are made before, during, and after prescribed fires (high realism, low replication), to laboratory bench approaches where small amounts of fuel are combusted in highly controlled settings (low realism, highly replicable) EXPAND ON GAPS & REALISM/REPLICATION TRADEOFF (Fernandes and Cruz (2012)).

Fire ecology experiments in the field often only manipulate the fuel load or type, necessarily sacrificing some realism in fuel structure. Fuels are often piled horizontally even though fuel complexes are typically more heterogeneous with substantial vertical structure that affects fire behavior (Loudermilk et al. (2014)). For example, in a grass-savanna landscape Bowman et al. (2017) piled fuels horizontally for a field experiment examining how fine fuel loads of different types affected fire intensity and survival of tree saplings. They found that sapling mortality increased with fire intensity (maximum temperature

at 5 cm). Fire intensity increased with fuel load, and grass-only and grass-litter fuel complexes produced greater fire intensities than litter-only fuels. Similarly, Thaxton and Platt (2006) altered fuel loads in a longleaf pine system to examine groundcover shrub survival. They added fixed amounts of fuel by piling either longleaf pine needles or pieces of pine wood, or removing a fixed amount of fine fuels from plots. The fuel addition treatments resulted in greater fire temperatures and shrub mortality compared to the removal and control treatments.

Each of these studies provide useful information that is applicable to the conditions of their study area and for the scale of the question, however, they also necessarily sacrifice some realism in fuel structure. JAUREGUIBERRY et al. (2011), Simpson et al. (2016), Wyse et al. (2016)

In this paper we present an experimental apparatus that can bridge the gap between making measurements of flammability at the lab bench and the limited replication of prescribed fires. The Fine Aboveground Biomass Incineration Organizer (FABIO) enables experimental manipulation of fuel load and structure at a relatively small but realistic and relevant scale of 1-m<sup>2</sup>. We expect our design will be most useful for grasses or grass-like fuels, but it could be used or adapted for other fuel types such as small shrubs and trees.

Fuel load has been shown to be a particularly important driver of combustibility, sustainability, and rate of spread.

Temperature metrics are influenced by fuel structure. In general, fuels with greater vertical arrangement will achieve higher maximum temperatures, but will also burn faster. Faster burning should result in less exposure to temperatures that cause plant tissue damage. We show these differences in maximum temperature and time above 100 °C for standing and piled fuels.

Also, density, dead:live ratio - the more flammable dead fuels can disproportionately influence fire behavior.

Grasses in particular fuel lots of fires, fuel loads are often increased in landscapes invaded by non-native grasses.

We present a methodology for maintaining realism in fuel structure in experiments where fine fuels with

53 typical vertical structure, e.g. grasses, are manipulated.

54 Using the exotic invasive cogongrass we illustrate how changing the fuel structure can substantially  
55 alter flammability characteristics.

56 It can be deployed in the field or in a more controlled “laboratory” setting.

## 57 **METHODS**

### 58 **Study site**

59 We harvested ~50 kg of standing cogongrass from an invasion at the Biven’s Arm Research Station  
60 (BARS), Florida, USA. The fuel was stored in a shed for 48-hours to protect it from rainfall, and then  
61 spread outside in a cleared area to dry for ~72 hours. We raked through the pile each day to increase  
62 drying, while carefully maintaining stem orientation in the same direction. We found that consistent  
63 stem orientation was more efficient for weighing and loading fuels vertically into the FABIO.

#### 64 1. Study Species

65 a. Collection of materials

66 b. Drying to a “constant” fuel moisture

#### 67 2. Burning Location

68 a. BARS

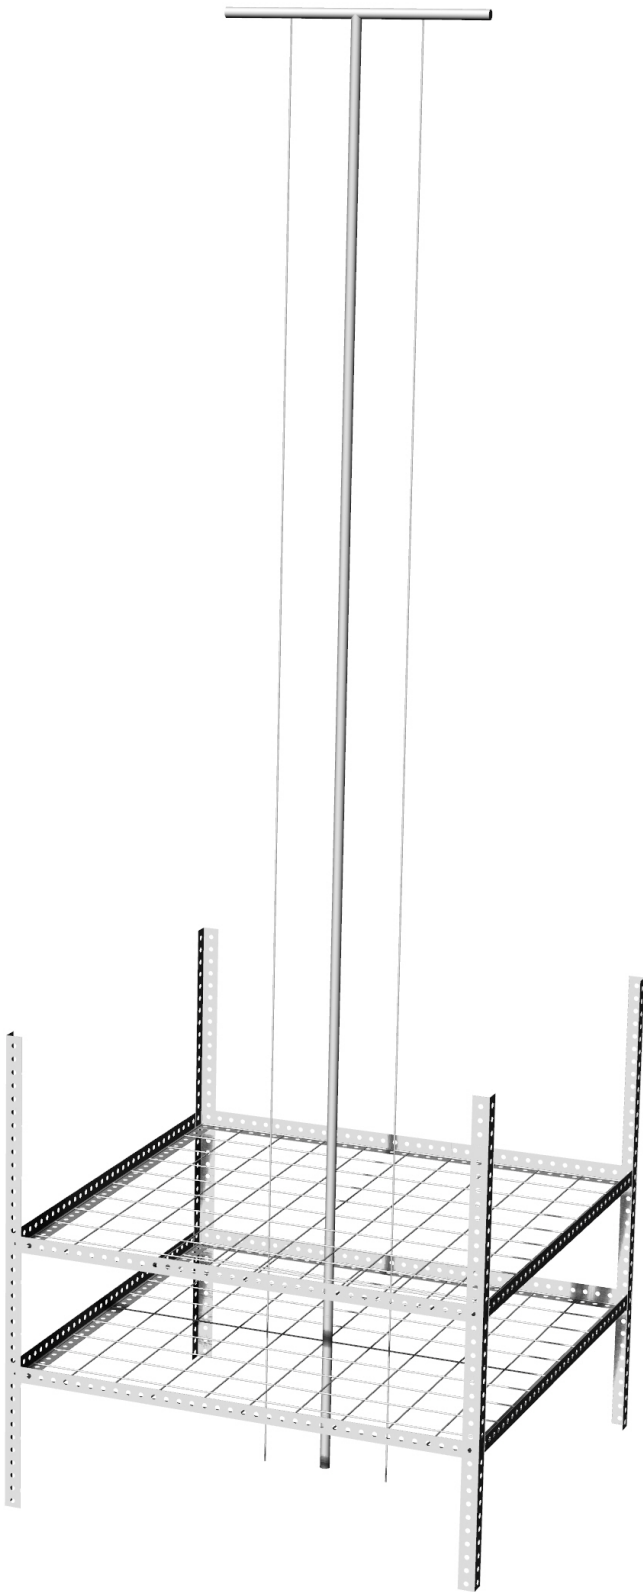

69 b. Weather measurements

70 i. Kestrel data

#### 71 3. Experimental treatments

72 a. Piled vs Standing

- 73           b. Number of burns
- 74               i. Blocked by day
- 75   4. Flammability measurements
- 76           a. All fires were ignited with a drip torch (Brand XX style XX)
- 77               i. All were lighted as head fires
- 78               ii. If failed to burn, was attempted 3 times from 3 sides before deemed a failure.
- 79           b. Fire temperature was measured every second with XX type thermocouples
- 80               i. Locations of sensors
- 81               ii. Determined maximum temperature
- 82               iii. Determined time above 100C
- 83           c. Rate of spread
- 84               i. 50cm distance and stop watch
- 85           d. Flame height
- 86               i. String soaked in Foscheck
- 87           e. Remaining biomass was collected to determine percent consumed
- 88   5. Statistical Analysis

## 91 Data collection and analysis

92 Our experimental design was to conduct six burns, three piled and three standing, for each of five fuel  
 93 loads (250 g, 500 g, 1000 g, 1500 g, 2000 g) spanning the range of cogongrass biomass observed from  
 94 field measurements across Florida, USA.

95 Thermocouple sensor specs Thermocouple logger specs

96 Weather data was recorded at a two second interval during fires using a Kestrel 5500 Fire Weather Pro  
 97 pocket weather tracker (Nielsen-Kellerman, Boothwyn, PA) mounted on a tripod to be ~1 m above the  
 98 ground.

99 We used linear regression to model the average maximum temperature and time above 100 °C at each  
 100 probe height, and the average flame height, rate of spread, and percent consumed from each fire. Fuel  
 101 load (mass) and fuel structure (piled vs. standing) were used as explanatory variables, with fuel load  
 102 treated as continuous. We tested the main effects and interaction of these variables. If the interaction  
 103 did not have a strong effect we fit a new model with only main effects. We report results from models  
 104 that

105 We applied a linear model where

$$y_i = \alpha + \beta_1 * biomass_i + \beta_2 * biomass_i * structure_i$$

## Fuel moisture

Across all fires fuel moisture content ranged from 4.6 to 19.6% (mean = 11.49±0.56%).

## Linear models of maximum temperature

The “maximum temperature” at each height is the average of the maximum temperatures from the three temperature probes located at that height. For some of the fires with the lowest amount of biomass (250 g) the probe temperature did not deviate from near-ambient (Fig. 3).

## 283 Rate of spread figure

284 Rate of spread was measured by recording the number of seconds it took the fire-line to travel 50 cm  
285 and then converted to units of  $\text{m s}^{-1}$ .

286

287 We used the statistical language R (R Core Team 2018) for all our analyses. These were implemented in  
288 dynamic markdown documents using `knitr` (Xie 2014, 2015, 2018) and `rmarkdown` (Allaire et al.  
289 2018) packages. All the multilevel models were fitted with `lme4` (Bates et al. 2015).

## 290 RESULTS

291 Trees in forest A grew taller than those in forest B (mean height: 25 versus 13 m). And many more  
292 cool results that get updated dynamically.

## 293 DISCUSSION

294 Discuss.

## 295 CONCLUSIONS

## 296 ACKNOWLEDGEMENTS

## 341 Key experimental fire ecology studies for reference

342 (Bowman et al. 2017) *Differential demographic filtering by surface fires: How fuel type and fuel load*  
343 *affect sapling mortality of an obligate seeder savanna tree.*

344 In this study, “Grass fuels had to be laid horizontally rather than standing vertically.” The context  
345 provided is that the native sorghum grass flattens easily after it dries and does not remain vertical  
346 throughout the dry season.

- 347 • This reads like a response to a reviewer comment, which might indicate a gap that the FABIO  
348 methodology can fill.
- 349 • Average flame height was measured “when the fire was within 15cm of the tree stem using a metal  
350 grid placed verically against a steel picket placed next to the stem.”

351 Additional references given where fuels have been laid flat when testing flammability:

- 352 • (???)
  - 353 – Built the “Bar-B-Q” apparatus to fill a need to quantify flammability of whole plants of  
354 many species
  - 355 – Quantified flammability characteristics of 34 species using “whole plant”
  - 356 – Fuels are still burnt horizontally, so no vertical structure
  - 357 – Length of fuel limited by size of burning surface
- 358 • (Simpson et al. 2016)
  - 359 – Assessed flammability of 25 savanna grass species
  - 360 – five plant traits: biomass quantity, biomass density, biomass moisture content, leaf surface-  
361 area:volume ratio, leaf effective heat combustion
  - 362 – related plant traits to three components of flammability: ignitability, sustainability, com-

bustibility at leaf and plant scales

- Results: total above-ground biomass drove combustibility and sustainability - high biomass was more intense for longer; moisture content was main driver of ignitability and also reduced combustion rate; estimates of whole-plant combustion rates showed >20-fold variation; Showed that there was significant variation between species in flammability at the plant-level and leaf-level

- (Wyse et al. 2016)

*All of these studies assessed flammability of multiple species, or multiple fuel complexes.*
